Components with Swift. It introduces concepts and code that are required for building bridge components with Android. Don't forget to take advantage of the code checkpoint for starting this chapter, found in the `ch08_00` directory.

The good news is that you'll reuse most of the JavaScript and Ruby code from the previous chapter. Here, you'll shift your focus to the Kotlin code because, well, there's a lot of it. You'll write close to 100 lines of Kotlin code in this chapter.

So, why do we need so much Kotlin when we accomplished the same on iOS with half as much Swift? The short answer is that Android can be much, much more verbose than iOS. And because its roots are Java-based, there are often additional layers of abstraction and configuration needed to do seemingly simple things.

But the magic of bridge components means you won't need to touch the native code to add the button to *new* pages. All that's required for that is a few lines of HTML markup with the right `data-*` attributes.

Following the same cadence as in the previous chapter, you'll start by creating a simple native component to ensure that everything is working as expected. You'll then progressively enhance it with more features, like dynamic text and an image, with the goal of making your hybrid app feel more native. And, as in the previous chapter, you'll keep the configuration on the server so the app remains flexible. Let's get to work!
