Generate and Upload a Signed App Bundle

Before you generate a bundle, let's make sure a physical Android device can access the server running on our Mac. You already learned this lesson when working on your iOS build here—no need to demonstrate it again.

Update `baseURL` for Release Builds

Android uses build variants[69] to represent different versions of your app that you can build. They are configured using a specific set of rules to combine settings, code, and resources configured in your build types. You'll use build variants to set a different `baseURL` for debug (when run in the emulator) vs. release builds (when signed and uploaded to Google Play).

Start by opening the app's `build.gradle.kts` and create a second build type, debug, under the `buildTypes` section.

ch09_05/android/app/build.gradle.kts

```
    // ...

    android {
        // ...

        buildTypes {
»           debug {
»           }

            release {
                isMinifyEnabled = false
                proguardFiles(
                    getDefaultProguardFile("proguard-android-optimize.txt"),
                    "proguard-rules.pro"
                )
            }
        }

        // ...
```
