building the core infrastructure needed to receive and persist these tokens to the Rails database.

Create the Notification Token Model

You'll keep track of a user's notification tokens with a new database table and record. We'll then use this to know *where* to send the notifications. Switch to the `rails` directory and generate the migration and model with the following:

```
bin/rails generate model NotificationToken \
  user:references! token:string! platform:string!
```

This creates a `NotificationToken` record that belongs to a `User`. It has a `token` column, the notification token from the device, and a `platform` column, to differentiate between iOS and Android devices. The three exclamation points (`!`) ensure that these columns cannot be null, adding `null: false` to the migration. Run the migration with `bin/rails db:migrate`.

Open `rails/app/models/notification_token.rb` and add the following validations. These ensure we always have a `token` and, for now, only for iOS devices. We'll add FCM later in the Android section.

ch10_06/rails/app/models/notification_token.rb

```
  class NotificationToken < ApplicationRecord
    belongs_to :user

»   validates :token, presence: true
»   validates :platform, inclusion: {in: %w[iOS]}
  end
```

Next, create the inverse association to the `NotificationToken` on the `User` model. A user can have more than one token because they can sign into the app on multiple devices and we want to notify each device.
