Recapping Push Notifications

You just learned how to implement push notifications across both mobile platforms.

On the clients, you kicked off the authorization request from a bridge component that's triggered when the user signs in. Then, when accepted, the notification token is POSTed to the server via a view model. Finally, when the notification was tapped, you built a URL from the `path` and deep linked to it via a `Navigator`.

On the Rails side, you learned how to set up Noticed to send notifications via APNs and FCM. You created a `Notifier` subclass to contain all of your notification logic, like only sending notifications to registered devices and embedding the `path` in the payload. And you're keeping your authorization tokens secure by storing them in Rails credentials.

With this scaffolding in place, you can further improve your notifications, *all from the server.* You could add a second line of text via `subtitle` on iOS[89] and `body` on Android.[90] Let's say you add the ability to comment on hikes. Create a `NewCommentNotifier` and start sending notifications—no additional client code needed. Even deep linking to a new `path` will work.
