

Rather than writing all the extra logic necessary for processing the information from the hash in the controller, it is better to delegate it into a class method to make the logic reusable and to keep our controller lean. Let's name the method `process_omniauth` and call it from our controller using the following code:

```
class OmniauthCallbacksController < Devise::OmniauthCallbacksControll
er
  def twitter
    user = User.process_omniauth(request.env["omniauth.auth"])
  end
end
```

When using the database authentication scheme, users will have to supply their username and password for authentication. This is not the case in a remote authentication scheme, because the third-party service will be the one that helps us in authenticating our users. Unfortunately, if we previously had a username and/or e-mail as the user's unique identifier in our database, our users won't be supplying that anymore. Instead, we have to look for other alternatives as the unique identifier. Luckily, Twitter supplies a `uid` value, which contains the unique user identifier that we can use.

We will store `uid` in our database within columns called `uid`. We will also store the provider name to indicate which authentication provider our users use in a column called `provider`. Let's create a migration for these new additions using the following commands:

```
$ rails g migration add_omniauth_to_users provider:string uid:string
$ rake db:migrate
```
