```
const area(thing: Square | Triangle | Circle): number {
  if (isCircle(thing)) {
    return PI * 2 * thing.radius
  } else {
    return thing.width * thing.height
  }
}
```

This code is bug-for-bug compatible with the previous snippet in that all objects deemed a `Circle` will go down the `if` branch, and all not-`Circle` objects will go down the `else` branch.

There are some clear limitations in doing type guards based on whether a single attribute is present or absent. As in our example, there might be multiple types with the same attribute and therefore, the type check might not be exact enough.

TypeScript, however, is extremely flexible in how it allows you to signal types, and while the type guards we've looked at in this section can be great, especially when dealing with external code, we do have other options.
