we used earlier. Personally, I think I'd stick to string literals—they seem less complex to me—unless there was some clear readability reason why the enum was better (for example, if there were several groups with overlapping set names and you wanted to ensure they were explicitly made distinct).

It's worth noting that, as written currently, the ticket status values coming from the server are still strings, so this version still works with the server, but the previous version where the enums were numbers won't. It's also true that changing the values from numbers to enums doesn't affect other uses of `TicketStatus`; anything that is looking at values like `TicketStatus.Held` will still work no matter what the type of the underlying value is.

To answer your next question, yes, you can have enums where some of the values are strings and some of the values are numbers. You can also have enums where the values are computed at run time. Please don't do either of those things. You only get the full value of enums as a type guard if all the values are set at compile time.
